KEYWORDS Abstract Background/purpose: Artificial intelligence (AI) has been widely used in medicine, including orthodontics. The aim of this study was to investigate the training process of a Artificial intelligence; cascaded Convolutional Neural Network (CNN), built for landmark detection on various quali-Automation: ties of lateral cephalograms and to determine the speed, reliability and clinical accuracy of an Cephalometry: algorithm for orthodontic diagnosis. Clinical decision-Materials and methods: The CNN model was trained on a total of 1600 lateral cephalograms. making; After each training datasets (input of 400, 800, 1200, 1600 images) were added, the model was Diagnosis; evaluated on a test set containing 78 images of varying quality. We measured the accuracy of Computer-assisted Al-based landmark detection by statistical analysis of intra- and interexaminer distance errors, as well as examiner versus model predictions, furthermore by prognosis of consecutive diagnostic failures. Results: There was a clear improvement in time efficiency (5.25 min), and substantial improvements were observed during the training process. In terms of accuracy, based on Euclidean distance error measurements, the best model provided more consistent dot tracing than two different examiners or the same examiner on two different occasions. Angular (0.05° -1.86°) and proportional (3.14%) errors, measured by the best model, were considered clinically acceptable. Conclusion: The application of a proper AI-algorithm for orthodontic cephalometric analysis results in lower variability between models than the variability observed among experts. Al predictions supported the examiners in finding the correct location of the specific landmarks more accurately and in less time as the training of the automatic prediction model improved. Further research could investigate the therapeutic consequences.

Introduction

Machine Learning (ML) plays a crucial role in a wide range of modern professions, including medicine and orthodontics.^{1,2} Technological innovations are the driving forces behind the rapid advancement of modern dentistry, as reflected in studies of the last decades, focusing on the use of Artificial Intelligence (AI) tools to optimize particular diagnostic workflows.^{1,3}

Numerous reviews show promising results in the application of AI in the early prediction of treatment needs, in determining the demand for orthognathic surgery or tooth extraction, in predicting cephalometric landmarks on 2D or 3D radiographs, as well as in identifying maturational properties of a growing patient.²⁻⁴ The reliability of these Al-assisted software applications is influenced by several factors; beside others, by the quality of the input dataset, the number of training cycles of the algorithm, and the characteristics of the algorithm itself. According to the latest cephalometric study in Journal of Dental Sciences, shared by Lee et al.,⁴ the standardization of manual landmark detection, image quality, and image sample might affect tool performance. Kim et al.⁵ highlight that the variability of errors in these models built for automated cephalometric analysis goes beyond individual landmarks, algorithms, or training image quantities, but also identifies inconsistencies across institutional outcomes.⁵

Statistical analysis of AI-assisted cephalometric evaluations have been conducted using various algorithms trained on diverse quantities of training sets. 5-7 Some studies show favorable outcomes even with limited data (n = 1028),⁶ and others achieve comparable results with larger input datasets (e.g. n = 1792 or n = 3150).^{5,7} According to Kang et al.,⁸ the mean distance error in determining cephalometric landmarks by different AI-algorithms ranges from 1.1 to 4.09 mm, based on findings from 3 reviews, summarising more than 165 studies on the topic.⁸ Distance errors between manually annotated and model-predicted landmark coordinates are typically defined as Euclidean distances.^{5,9} Assessing the clinical relevance of landmark detection accuracy in cephalometric analysis is challenging as subjective diagnostic estimations of clinicians often contain meaningful errors, even with repeated evaluations of the same examiner. Ana R. Durao et al.¹⁰ have revealed that despite a considerable number of publications on cephalometric analysis (n = 968), only a limited number of studies have examined the validity and reliability (n = 16) of 2D landmark detection on cephalograms, as articles prioritise 3D assessments.¹⁰ The integration of AI prediction models into everyday processes has substantially altered this landscape over the past decade.^{11–13} However, there are still insufficient data on diagnostically and therapeutically relevant metrics measured by various tools for cephalometric analysis.

Most studies examine a maximum of 20 landmarks and disregard difficult-to-detect profiles and tangent points that

are used by specialists in clinical practice but can degrade statistics. This study considers 48 cephalometric landmarks (Table 1) and compares evaluations of images of varying quality, using models trained on four datasets of different sizes. The evaluation with these landmarks covers dental, dentoalveolar- and alveolar deviations examined, based on the Rickett's and Hasund analysis, and can be used to analyse the entire skull, jaw relationships, dentition and profile.

Among the experiments with available software solutions, the model we tested is notable for its comprehensive, criteria-based assessments that directly investigate the physician-AI relationship. To minimize clinician-induced errors in landmark detection accuracy, measurements were repeated eight times; twice by two independent experts on four separate occasions.

In this study, our aim was to prove the significance of the quality and quantity of training data for the accuracy and the time efficiency of a ML model (hereafter'AI') in clinical applications, using a relatively large dataset of 1678 images. However, we hypothesised that after a certain amount of training data, further increasing the training datasets (TD) yields marginal improvements. Our objective

The scaling process in this study follows established methodologies for image analysis:

Scaling explanation:

Score 5: Adequately assessed, high-resolution image (total: 2). Score 4: Adequately assessed, high-resolution image; however, the presence of orthodontic appliances during image acquisition and other factors may have contributed to visible blurry areas, though these are minimally distracting and did not affect analysis integrity (total: 15).

Score 3: Blurred double lines hinder accurate area evaluation, suggesting potential patient movement during image acquisition, complicating analysis (total: 42).

Score 2: Image quality is sub-optimal, with insufficient detail, making it challenging to accurately identify cranial or profile landmarks (total: 17).

Score 1: Image resolution is inadequate, resulting in poor quality and insufficient detail, thereby making it difficult to accurately identify both cranial and profile landmarks (total:2).

was to show on clinically relevant data that cephalometric landmark predictions of an AI-model facilitate more accurate angle and proportional calculations, thereby enabling a proper orthodontic diagnosis in a shorter time. It presents the novel finding, that given sufficient and high-quality data, an AI-model can serve as a precise diagnostic tool in both spatial and temporal contexts, outlining its advantages and potential drawbacks.

Materials and methods

The study was approved by the IRB of Semmelweis University, Budapest, Hungary (SE-RKEB number:112/2021). Due to the retrospective nature of the study, the ethics committee waived the requirement for informed consent.

ARTICLE IN PRESS + MODEL Journal of Dental Sciences xxx (xxxx) xxx

Using four different dataset quantities, we trained a new AI-model developed by Ceph Assistant Ltd. (Budapest, Hungary) and evaluated it on a test dataset. We expected the accuracy and time efficiency of the model to improve as the TD increased, reflecting this progress in our results.

Data collection

Regardless of whether the radiographs showed dentures or orthodontic appliances, a total of 1678 2D lateral cephalometric images (2485 \times 2232), all uniformly downsampled to a pixel size of 512 \times 512, were randomly selected and anonymously downloaded from the Onyx-Ceph3TM (Chemnitz, Germany) server at Semmelweis University, Department of Paediatric Dentistry and Orthodontics (Budapest, Hungary)¹⁴ (hereafter'Clinic'). Altogether, 1600 cephalograms were manually (using mouse-controlled cursor) evaluated by the orthodontists working at the Clinic based on Hasund and Rickett's analysis in the OnyxCeph3TM software (Fig. 1). Calibration and resolution elements of the recordings were checked, and the cephalometric evaluations were verified by three experienced professionals. The X and Y coordinates of each of the 48 landmarks were saved separately, exported and used to train the Ceph Assistant Al-algorithm.¹³

A test dataset consisting of 78 cephalograms was used, randomly selected from a total of 1678 images. To prove the representativeness of the test dataset, cross-validation was performed on a set of 39 (50 %) and 20 (25 %) elements randomly selected 10000 times from the 78 test samples. We calculated the percentage fluctuation of prediction for comparing AI versus AI-corrected and AI versus gold standard as well, to confirm the role of sample selection data over prediction or any reference.

Training process and technical features of four prediction models with varying training levels

This study utilised the Ceph Assistant¹³ AI-architecture, a Convolutional Neural Network (CNN) specifically developed for landmark localization in lateral cephalometric images, as a reference AI-based cephalometric solution. The TD

Estimation process	Mean	Std	Min	50%	Max
Fully manual	315.91	32.51	254.71	310.99	407.14

Figure 4 L2 distances between the coordinates of the manual average and AI-generated landmarks by varying amounts of training data (TD).

consisted of a total of 1600 lateral cephalograms, together with their corresponding preliminary manual evaluations stored in .xls/.xlsx format. The model underwent training on four distinct datasets, containing 400/800/1200 and 1600 images, respectively. During each training process, the model received cephalometric images as input and the manually recorded location data of the 48 landmarks as output.

Testing at four different levels of the model

During testing, the dataset was automatically analysed by the AI-model following each training set (TD = 400/800/1200/1600 cephalometric images). Once the test set was processed by the AI-algorithm, the senior examiner manually corrected landmark errors using mouse-controlled dot tracing. Manual evaluation of the dataset was performed using a test environment of the Ceph Assistant (Fig. 2), configured directly for this experiment. The evaluation was performed by two experts with 4 (medior) and 10 (senior) years of clinical orthodontic experience. The 78 cephalograms included images of 41 female and 37 male patients with an average age of 13.8 years. Both manual and AI evaluations included 48 cephalometric landmarks of skeletal, dental and profile markers (Table 1). Time was automatically measured by the software.

Statistical analysis

A statistical analysis was performed on time efficiency and accuracy of landmark detection achieved by the different methods. After measurements were performed ten times (2"manual", 4"Al-corrected", 4"Al"), data were compared to the gold standard. The average of the landmark coordinates, corrected by the senior expert on four different occasions, was defined as the gold standard. It was found that the quality of the test images substantially influenced the decision of the experts on landmark positioning and

Journal of Dental Sciences xxx (xxxx) xxx

Distribution of L2 distances between manual average and AI-corrected landmark points

Figure 5 L2 distances between the coordinates of the manual average and AI-corrected landmarks by varying amounts of training data (TD).

time taken for evaluation. Therefore, experts graded images based on quality and statistical analysis was extended to detect differences. This included precise calibration to accurately compare different images. Table 2 shows that almost a quarter of the images were rated as either easy (score 4, 5) or difficult (score 1, 2) and 42 were rated as moderate (score 3). We employed the violin plot chart to show discrepancies in time measurements, as they can reveal clustering and roughness of distribution, providing additional information.¹⁵

Euclidean (L2) distances were considered for distance errors, as L2 performed better than Manhattan (L1) in research where directional information of the coordinates yielded less difference and relevance.^{9,16} Histograms and a box plot diagram were used to illustrate the comparison between manual versus AI-corrected, manual versus AIgenerated and AI-generated versus AI-corrected distances following each TD.

Results

Although the two references behaved in fundamentally different ways, the percentage fluctuation values were remarkably similar in both the semi-rotation (3.07 %; 3.095 %) and the guarter rotation statistics (5.15 % and 5.29 %). According to these cross-validation values, our test dataset is representative, assuming that the cephalograms cover all relevant clinical cases.

Time spent on evaluation

Comparative analysis was performed between the time spent by the two experts on manual cephalometric analysis and the time by the Ceph Assistant model for automatic evaluation, followed by correction of the senior examiner. Manual evaluations required an average of 315.48 s (sec)

Figure 6 L2 distances between the coordinates of the AI-generated and AI-corrected landmarks by varying amounts of training data (TD).

more than the model predictions (0.43 s) per sample. The first four violin plots in Fig. 3 show that the mean time (104.12-167.02 s) required to correct predictions improved substantially as the AI-algorithm was upgraded with each training set.

Distance errors of cephalometric landmark tracing methods

We analysed 2D coordinate data (X,Y) of cephalometric landmark predictions (hereafter "AI") on digital X-ray images after training on all four TDs. We examined the relevance of these predictions to the average of manual corrections of the senior examiner, defined as the gold standard.

Initially, AI was compared to the gold standard (Fig. 4). Mean L2 distances varied between 2.43 and 2.88 mm (median:1.94–2.44 mm) across the four different training levels. Results indicate that the increasing number of training samples (up to TD = 1200) substantially improved the accuracy of the model. Similar results were observed when AI-assisted manual corrections (hereafter "AI- corrected") were treated as independent variables, with a slightly reduced mean L2 distance of 1.75-2.10 mm (median:1.31-1.71 mm) that remained consistent after TD = 800 (Fig. 5). The noticeable increase in standard deviation after the second measurement was due to variations in decision-making related to the individual circumstances of the examiners in both cases.

In addition, we observed substantial agreement between the AI and the AI-corrected landmarks (Fig. 6), with a mean L2 distance ranging from 1.36 to 2.04 mm (median:1.05–1.76 mm), depending on the training level of the model. This highlights the influence of AI on decisions of examiners during manual dot tracing. To eliminate errors due to the subjective bias of a single examiner, a second examiner performed an independent manual evaluation.

Comparisons were made between the measurements of the senior and the medior examiners, as well as between the landmarks observed by the senior examiner and the Al-corrected after TD = 1600. The mean L2 distance between the two examiners, representing the inter-examiner error, was 2.02 mm (median:1.66 mm) (Fig. 7), whereas the mean intra-examiner variability was 2.10 mm (median:1.68 mm)

Figure 7 L2 distances between the coordinates of the landmarks detected manually by the two examiners.

(Fig. 8). Furthermore, the results show that initial AI prediction aids the decision making of the clinician, as illustrated by the box plot diagram in Fig. 9. In this case, L2 errors were also evaluated based on the training level of the model and on the complexity of the images (Table 2).

The L2 distance errors of the best models are detailed in Tables 3 and 4. The primary difference between these tables is that in Table 3, model predictions were compared to the gold standard, which is the average of four corrected evaluations by the senior examiner. In contrast, Table 4 shows L2 landmark errors relative to the single correction made after using the latest tool of the model. While the model performs well in comparison to the average, the senior examiner shows larger displacements to correct the prediction than what would be necessary according to the gold standard. On the one hand, this suggests that the actual corrections are smaller than the average. On the other hand, this can be a sign of bias in Al-assistance, as the expert can be influenced by the predictions. However, the placement of fully manual and AI-assisted landmarks is practically acceptable.

When L2 errors were examined for the Al-corrected landmarks after TD = 1600, the highest distances were measured by Condylon (4.03 mm), while the lowest was

measured by the center of Sella's entry (1.1 mm) (Table 3). Slightly modified, when the L2 errors were compared between the AI-corrected and the model predicted landmarks after TD = 1600, the highest errors were observed by Basion (3.41 mm), while the lowest errors were found by the center of Sella's entry (0.22 mm) (Table 4).

Errors in clinically relevant diagnostic values

In orthodontics, diagnostically and therapeutically relevant data (angles, proportions) typically involve at least three landmarks. Therefore, L2 landmark errors of X and Y coordinates provide limited insight into clinical relevance. We performed calculations to assess how L2 discrepancies were reflected in specific orthodontic reference angles or proportions. The mean angular difference between the three landmarks predicted by the model after TD = 1600, and those determined manually ranged from 0.17° to 1.09° on average (Table 5). Similarly, angular difference was valued from 0.05° to 1.86° when angles were determined by four cephalometric landmarks (Table 6). Rational divergence was observed in the proportion of lower and upper facial heights, determined by three landmarks (N, SnA, Me) with the prediction showing a difference of 3.14% from the gold standard ratio after TD = 1600 were completed on the algorithm.

Discussion

We maintained high-quality training and evaluation data by following standardized protocols and consistent measurement procedures while including samples with diverse medical and imaging characteristics to ensure comprehensive domain coverage. Additionally, we conducted thorough statistical analyses using medically relevant metrics and perspectives to support the development of a reliable AI model.

In terms of time efficiency, modern prediction tools are advantageous for cephalometric evaluation. Even with corrections of landmarks predicted by models trained on smaller datasets, the evaluation took less than half the time of fully manual dot tracing. In terms of accuracy, the mean L2 distance error of AI after TD = 1600 was 66 % of the difference between the manual tracing of the two experts using the same metric, showing that the latest model provided more consistent dot tracing than two different examiners or the same examiner on two different occasions. These results confirm the hypothesis that examiners make minor corrections to AI, indicating that predictions influence the decisions of the examiner during cephalometric analysis; however, these potentially biased placements are still medically correct, and were even closer to the gold standard, indicating that model assistance may not only speed up but also improve manual prediction. The extension of TD improved model precision, but these small improvements are clinically insignificant, as the tool noise is lower than examiner noise. Still, the use of higher quality models is beneficial as they yield considerably better results with less correction. Previous studies suggest lower intra- and inter-examiner variability compared to our findings, which may be due to variations in exclusion

criteria and the increased number of landmarks incorporated in our study. $^{17,18} \,$

According to Wang et al.,^{19–21} landmark detection within 2 mms is clinically acceptable. Although our model slightly exceeded this criterion on average, the median prediction distance is well inside this threshold, probably due to the fact that our evaluation scheme included much more difficult landmarks than many other studies. Furthermore, our calculations of clinically relevant angular and ratio errors between AI and human dot tracing showed promising results.

Considering these references, we can claim that our best prediction model can serve as an accurate baseline for orthodontic analysis on lateral cephalograms, substantially speeding up the workflow of orthodontic diagnostics.²² Given the large amount and high quality of data available through this method, a fully autonomous system could be developed that requires no corrections. Further research could investigate the consequences of evaluation errors and biases in clinical therapy. Future research should focus on training Al with malocclusion-specific datasets and integrating diverse evaluation methods to create a robust, precise, and efficient Al-driven diagnostic system for clinical practice.

Declaration of Generative AI and AI-assisted technologies in the writing process

During the preparation of this article the authors used ChatGPT in order to improve the readability and language of the paper. After using this Generative AI-tool/service on certain sentences and expressions, the authors reviewed and edited the content as needed and take full responsibility for the content of the publication.

Declaration of competing interest

The authors have no conflicts of interest relevant to this article.
